22 **Abstract**

23 We present recent observations of Sudden Phase Anomalies due to subionospheric
24 propagation anomalies produced by solar X-ray flares. We use the new South America
25 VLF Network (SAVNET) to study 471 ionospheric events produced by solar flares
26 during the period May, 2006 to July, 2009 which corresponds to the present minimum
27 of solar activity. For this activity level we find that 100 % of the solar flares with a X-
28 ray peak flux above $5 \times 10^{-7} \text{ W/m}^2$ in the 0.1 - 0.8 nm wavelength range produce a
29 significant ionospheric disturbance, while the minimum X-ray flux needed to do so is
30 about $2.7 \times 10^{-7} \text{ W/m}^2$. We find that this latter minimum threshold is dependent on the

31 solar cycle, increasing when the Sun is more active, thus confirming that the low
32 ionosphere is more sensitive during periods of low solar activity. Also, our findings are
33 in agreement with the idea that the ionospheric D-region is formed and maintained by
34 the solar Lyman- α radiation outside solar flare periods.

35 **Key words:** VLF technique, solar activity, solar flares, solar activity cycle, SPAs

36

37 INTRODUCTION

38 The monitoring and analysis of Very Low Frequency (VLF; 3 - 30 kHz) propagation
39 anomalies is a powerful tool to study the low altitude Earth's ionosphere like the diurnal
40 C and D regions at an altitude range of 60 - 70 km. This portion of the ionosphere is not
41 accessible to stratospheric balloons and well below most satellites orbits. VLF waves
42 propagate over long distances within the Earth - Ionosphere Waveguide (EIW), and
43 their characteristics in phase Φ , and amplitude A, inform about the electrical properties
44 of the waveguide's conducting boundaries, i.-e. the surface of the Earth and the low
45 ionosphere plasma [Wait and Spies 1964].

46 The main cause for the presence of the daytime ionospheric D-region is the solar
47 Lyman- α (1216 Å) radiation [Nicolet and Aikin, 1960] which progressively increases
48 the electrical conductivity in the 70 - 90 km altitude range by ionizing nitric oxide (NO)
49 molecules as the Sun rises. As a result, a relatively stable reflecting layer is formed at
50 about 70 km which lasts under solar daytime conditions. At night, electron
51 recombination processes overcome the ionization and the D region disappears when the
52 reflecting layer moves to about 90 km and is now formed by the bottom of the nighttime
53 E region. Therefore it is useful to study the properties of the low ionosphere by the
54 mean of parameters which characterize the electrical conductivity (height) profile: the
55 reference height H' (in km) and the conductivity gradient β (in km^{-1}) [Wait, 1959; Wait
56 and Spies 1964]. The reference height H' is the altitude where the electrical conductivity
57 is constant at $2.5 \times 10^5 \text{ s}^{-1}$ and the conductivity gradient (or sharpness) informs how fast
58 the conductivity changes with height.

59 Departure from the above described quiescent situation occurs when there are
60 ionization excesses in the low ionosphere. The reasons for that can be external sources
61 of radiation like X-ray solar flares [Bracewell and Straker, 1949; Kaufmann and Paes de

62 Barros, 1969; Muraoka et al. 1977], X-ray bursts from remote objects like magnetar
63 bursts [Kaufmann et al. 1973; Rizzo Piazza et al. 1983; Tanaka et al. 2008; Raulin et al.
64 2009a], or meteor showers [Chilton, 1961; Kaufmann et al. 1989]. The electrical
65 properties of the EIW can also change due to perturbations from the inside of the
66 waveguide like atmospheric lightning causing precipitation of initially trapped electrons
67 [Cummer, 1997], Transient Luminous Effects (TLEs) like red sprites and elves [Inan et
68 al. 1995; Pasko et al. 1995], and natural phenomena related to seismic-electromagnetic
69 effects [Hayakawa et al. 1996].

70 During solar flares when the solar active regions plasma is heated up to few tens of
71 millions degrees, increases of a few orders of magnitude of the solar X-ray emission are
72 observed at the Earth orbit. The photons with $\lambda \leq 2 \text{ \AA}$ can reach altitudes below the
73 reference height H' [Pacini and Raulin, 2006], producing significant ionization
74 enhancements in the low ionosphere which result in variations of one or both of the
75 Wait parameters. Lowering of H' is observed in the phase of long distance propagating
76 waves as Sudden Phase Anomalies (SPA), that is, as advances of the phase of the
77 transmitted waves. The SPA intensity $\Delta\Phi$, depends on the X-ray flux (P_x) and spectrum,
78 and time of occurrence of the solar event as well as on the characteristics of the VLF
79 propagation path. From this relation it is generally possible to infer the lower soft X-ray
80 flux (P_{xm}) needed to produce a ionospheric event, and P_{xm} can be further used to deduce
81 the electron density enhancement in the D-region at the time of solar flares, and/or to
82 improve the determination of recombination coefficients which are generally poorly
83 known. For space weather studies, and in particular for the present study it is important
84 to know whether P_{xm} depends on the level of solar activity, and thus confirm that the
85 low ionosphere sensitivity changes with solar activity conditions (Pacini and Raulin,
86 2006).

87 In this paper we study the relation between solar X-ray flares and the subsequent
88 ionospheric disturbances detected by a new VLF instrumental facility, the South
89 America VLF Network (SAVNET). SAVNET is an international project between
90 Brazil, Peru and Argentina, dedicated to monitor the effects of the solar activity in the
91 low ionosphere and in particular over the South Atlantic Magnetic Anomaly (SAMA)
92 region. In the next section we briefly present the instrumentation used and describe the
93 methodology adopted as well as the observational results we have obtained. We then
94 discuss these results before presenting our concluding remarks.

96 1. INSTRUMENTATION, DATA ANALYSIS AND OBSERVATIONAL RESULTS

97 The SAVNET installation has been performed in the 2007 - 2009 time period, and
98 the array is currently composed of eight VLF tracking stations located in Brazil, Peru
99 and Argentina. In Figure 1 we show the location of the SAVNET receivers bases as
100 well as the positions of the transmitters. Examples of VLF propagation paths, part of
101 Great Circle Paths (GCP), are shown from the transmitters NAA and NPM. Each
102 receiver base is composed of three electromagnetic sensors and the VLF signals
103 received from the powerful transmitters are amplified and then digitized using a
104 commercial audio card. The crystal of the audio card provides a clock signal which is
105 locked to a GPS internal clock signal (1 PPS), and this ensemble provides a phase
106 determination of the incoming wave without any drift. The resulting phase signal
107 presents a precision (r.m.s) of about 0.05 – 0.07 microsecond, which corresponds to
108 about less than 1 degree depending on the frequency of the incoming VLF wave. In this
109 paper we use the data base from the 13060 km long VLF propagation path between the
110 transmitter NPM (Hawaii, 21.4 kHz) and the receiver ATI (Atibaia, SP, Brazil), path
111 which is hereafter mentioned as NPM - ATI. For more details on the SAVNET
112 instrumental setup and scientific goals see Raulin et al. [2009b, 2009c].

113 The solar flare data base used in this paper is composed of soft X-ray fluxes from
114 GOES detectors which record the solar radiation in two photon energy channels, 0.1 –
115 0.8 nm and 0.05 – 0.4 nm (NOAA, Space Weather Prediction Center). The fluxes
116 detected by GOES instruments mainly come from the thermal free-free emission
117 produced in hot solar active regions, where the plasma temperature lies in the range 1 -
118 3 MK. During solar flares, soft X-ray fluxes are significantly enhanced by several
119 orders of magnitude due to an increase of the plasma temperature or the plasma
120 emission measure, or an increase of both.

121 Since May of 2006, 471 flares have been detected and ordered using the GOES
122 classification (GOES Class). This classification is based on the peak power P_x (W/m^2)
123 detected in the 0.1 – 0.8 nm channel, using the following rule and ranges: B - Class for
124 P_x in the range $10^{-7} - 10^{-6} W/m^2$; C - Class for P_x in the range $10^{-6} - 10^{-5} W/m^2$; M -
125 Class for P_x in the range $10^{-5} - 10^{-4} W/m^2$; X - Class for P_x greater than $10^{-4} W/m^2$.
126 Thus a C 1.5 GOES Class solar flare does present a peak flux of $1.5 \times 10^{-6} W/m^2$ in the

127 0.1 – 0.8 nm channel. From the original solar flare data base we removed those solar
128 events for which the mean solar zenithal angle, estimated along the whole VLF
129 propagation path was greater than 90° . For the East-West oriented propagation path
130 (NPM - ATI) used in this work, we also did not take into account the solar flares which
131 occurred right at, or close to the time of VLF modal minima, since it may mask the
132 phase advance observed by the VLF receiver. The criterion we have adopted for flare
133 detection using the 1 s time constant VLF phase signal corresponds to an increase of
134 about 1.5σ (rms) compared to the mean pre-flare phase.

135

136 As a result we present in Figure 2 one-hour sample cases of ten X-ray flares of
137 different classes from B to M GOES Class. The dash-dot lines show the 0.1 – 0.8 nm
138 soft X-ray flux time profiles which are compared to the VLF phase records (full line)
139 observed simultaneously. In each plot we indicate the mean solar zenith angle, χ ,
140 estimated along the whole path at the time of the peak of the solar event. It has been
141 computed by dividing each VLF propagation path in 100 parts and calculating for each
142 piece a solar zenithal angle χ_i ($i = 1, 100$). The χ is then calculated as the mean value of
143 the χ_i angles. The thick vertical lines in the left part of each panel represent a phase
144 excess of 15 degrees. Therefore Figure 2 gives an illustration of how the very low
145 frequency receivers from the SAVNET array observe solar flares of different X-ray
146 flux. Note in particular in the upper left corner the SPA associated with a small B 2.7
147 solar event, for which the phase advance was 2.5 degrees which corresponds to a phase
148 advance of $0.3 \mu\text{s}$ at the frequency of 21.4 kHz. Such a solar event is thus detected as an
149 increase of the phase of about 4σ .

150 The main result of this paper is shown in Figure 3 and is related to the capability of
151 detecting solar flare events using a VLF technique. We can define this ability as the
152 probability P that a given flare of X-ray power P_x produces a SPA. P is then obtained by
153 the ratio of the number of solar events detected in a given class to the total number of
154 solar events which occurred in the same class. The full line histogram shows the
155 probability of detecting solar flares with $\chi < 40^\circ$ as a function of P_x , and the dashed
156 histogram shows the same for flares with $\chi < 70^\circ$. The vertical thick bar indicates the
157 value of P_x for which the probability P becomes 100 %. Thus our results indicate that

158 solar flares with a peak X-ray flux $\geq 5 \times 10^{-7} \text{ W/m}^2$ (GOES B5 Class or higher) will be
159 detected with a probability of 100 % in the low ionosphere.

160 The lower detection limit, P_{xm} , which would correspond to the lower soft X-ray
161 power needed to produce a SPA is about $2.7 \times 10^{-7} \text{ W/m}^2$ corresponding to a GOES
162 class for which solar events are detected with a probability of 50%. A typical time
163 profile of such an event is shown in Figure 2 (upper left panels).

164 2. DISCUSSION

165 In the previous section we have shown the capability of the SAVNET instrumental
166 facility to detect solar flares, even small solar events of GOES Class B. We now
167 compare our findings with related earlier works.

168 A direct comparison of our results can be performed with those obtained by
169 Comarmond [1977]. The author studied about 520 solar flare events during a period of
170 high to medium solar activity levels between December 1968 and January 1971 using
171 the 6970 km long East - West oriented VLF propagation path NWC (Australia) -
172 TANANARIVE (Madagascar). When only the solar flares with $\chi < 40^\circ$ were taken into
173 account, a 75 % detection probability is achieved for P_x in the range $5.6 \times 10^{-6} - 1.0 \times$
174 10^{-5} W/m^2 (C 5.6 - M 1.0 GOES Classes), that is about one order of magnitude higher
175 than our results shown in Figure 3. The detection probability for smaller flares in the
176 range C 3.2 - C 5.6 was about 25 %. As we will discuss below the reason for this
177 difference is due to the level of solar activity at that time.

178 Most of the papers studying the relation between solar flares and the resulting
179 response of the low ionosphere using the VLF technique, deal with the correlation
180 between the X-ray peak power in a given photon energy range (P_x), and the phase ($\Delta\Phi$)
181 and/or amplitude (ΔA) changes which are subsequently observed [Kaufmann and Paes
182 de Barros, 1969; Comarmond, 1977; Muraoka et al. 1977; Pant, 1983; Pant et al. 1993;
183 Kaufmann et al. 2002; McRae & Thomson, 2004; Thomson et al., 2005; Pacini, 2006;
184 Raulin et al. 2006; Zigman et al. 2007]. In general the P_x versus $\Delta\Phi$ (or ΔA) plots do
185 present a good correlation for both variables and it is possible to identify the faintest
186 solar events detected by extrapolating the correlation towards these small events
187 deducing a minimum soft X-ray flux, P_{xm} . This procedure does not inform on the

188 probability of such events to produce an ionization excess in the low ionosphere
189 however it tells us that they were actually detected using the VLF tracking technique.

190 The result of the previously explained procedure is summarized in the Table 1
191 where we show the reference works, the VLF propagation path used and its length (L in
192 Mm) and the frequency of observation (in kHz). The values obtained for P_{xm} and the
193 corresponding classes are also indicated. Table 1 also shows the epoch of occurrence of
194 the solar events studied, and the level of solar activity at that time. This level has been
195 estimated from the composite Lyman- α time profile from 1947 to the actual epoch
196 [Woods et al. 2000] combining measurements and modeling results, being from 2003 to
197 the present time actual measurements from TIMED/SEE and SORCE space missions
198 [Woods et al., 2005; Rottman et al., 2006]. To obtain the mean value indicated in Table
199 1 (third column from left) we have performed an average of the Lyman- α photon flux
200 over the period of the solar flare observations.

201 Our results on the probability P are not strongly dependent on the solar zenith angle
202 χ . This is illustrated in Figure 3 for solar flares for which $\chi > 40^\circ$ and for solar flares for
203 which $\chi < 40^\circ$. This is in agreement also with previous works which found no
204 dependency with χ , for χ values below $60^\circ - 70^\circ$ [Kaufmann et al. 2002; Pant et al.
205 1993].

206 A clear indication from Table 1 is that the minimum soft X-ray flux needed to
207 produce a phase change during a solar flare is increasing as the level of solar activity is
208 higher. We illustrate this property in Figure 4 where we have plotted P_{xm} as a function
209 of the mean level of solar Lyman- α radiation using the referenced works and
210 corresponding numbers in Table 1. We can see a very good correlation which
211 emphasizes the fact that the low ionospheric response to solar photons is solar cycle
212 dependent, being more sensitive at times of low solar activity. Such property was
213 already shown in Raulin et al. [2006] and Pacini and Raulin [2006]. Similarly McRae
214 and Thomson [2000; 2004] found that the ionospheric reference height H' was higher
215 during solar activity minima, a fact that can also be interpreted as different ionospheric
216 sensitivity for different solar activity levels. The correlation shown in Figure 4 clearly
217 suggests that for a solar flare to be detected in the low ionosphere, the corresponding
218 ionization should overcome that due to the quiescent solar Lyman- α radiation. At the

219 same time, this result is in complete agreement with the hypothesis that the solar
220 Lyman- α radiation forms and maintains the undisturbed D-region [Nicolet and Aikin,
221 1960].

222 Finally we would like to mention the work of Muraoka et al. [1977] who found a
223 lower X-ray threshold, P_{xm} of 1.5×10^{-6} W/m² (C 1.5 GOES Class) when studying the
224 SPAs associated with ~ 45 solar flares in the period July 1974 - June 1975. For this
225 period the Lyman- α composite data show a mean photon flux of the order of 4×10^{11}
226 ph.cm⁻².s⁻¹ such that the corresponding point [4 ; 0.18] if displayed in Figure 4 will
227 appear well above the correlation line. A reason for that may be related to the
228 propagation path used which was a high latitude (> 40 degrees North), East-West
229 oriented path between the transmitter NLK and the receiver HCM located in Japan. For
230 about half of the year between October and March, the average (over the path length)
231 solar zenith angle is > 40 degrees, and it is greater than 60 degrees for the winter
232 months between November and January. We also note that in this study the authors
233 corrected the phase data using the minimum zenith angle over the VLF path rather than
234 its mean value. In this case, one certainly underestimates the phase changes $\Delta\Phi$ and
235 therefore may overestimate the value of P_{xm} deduced from the $\Delta\Phi$ versus P_x correlation
236 plot. Another reason may be related to the fact that no soft X-ray data were available for
237 the period studied by the authors, and P_x values were therefore indirectly derived from
238 F_{min} , i.e. the lowest frequency showing vertical ionospheric reflection which was
239 measured close to the location of the VLF receiver Sato [1975].

240 **3. CONCLUDING REMARKS**

241 In this paper we have presented VLF subionospheric propagation anomalies
242 associated with the occurrence of solar flares, using a new instrumental facility, the
243 South America VLF Network (SAVNET). In particular we concentrated on the
244 capability of the new instrument in detecting solar events during the period
245 corresponding to the present minimum of solar activity (2006 - 2009).

246 The results have shown that solar flares with an X-ray peak flux above 5×10^{-7}
247 W/m² (B 5 Class) in the 0.1 - 0.8 nm energy range are detected with a probability of 100
248 %, and that the lower detection threshold is around 2.7×10^{-7} W/m². Combining our
249 results with earlier studies obtained for different solar activity levels, we find that the

250 lower X-ray detection limit is an increasing function of the solar activity as
251 characterized by the mean solar Lyman- α photon flux. These results are coherent with
252 the idea that the quiescent diurnal low ionosphere at ~ 70 km is maintained by the solar
253 Lyman- α radiation [Nicolet and Aikin, 1960], and that it is more sensitive during period
254 of low solar activity.

255 Finally we note that the high sensitivity of the VLF diagnostic to detect
256 perturbation in the low ionosphere caused by solar flares, even small solar flares, may
257 serve to stimulate the search for signatures from other objects. As we mentioned in the
258 introduction of the paper, the SAVNET instrument has already detected perturbations
259 caused by Anomalous X-ray Pulsars (or magnetars). An earlier and famous example
260 was the flare of the Soft Gamma Repeater (SGR 1806-20) which occurred in 2004,
261 December 27 and which was widely described in the literature [Terasawa et al., 2005].
262 The interest in studying such objects lies in the fact that the energy output during a
263 given burst can exceed by 10 to 15 orders of magnitude that released during the largest
264 solar flares. Therefore a better description of the physical processes leading to this huge
265 liberation of energy depends on the derivation of good X-ray and γ -ray spectra. The
266 VLF technique can thus provide a way of better determining the low energy part of
267 spectra of celestial γ -ray flares, if they are intense enough to produce ionospheric
268 perturbations.

269 **ACKNOWLEDGEMENTS**

270 The authors thank two anonymous referees for comments and suggestions which have
271 improved the quality of this paper. JPR would like to thank funding agencies
272 MACKPESQUISA and CNPq (Proc. 304433/2004-7). FCPB thanks FAPESP (Proc.
273 2007/05630-1). The SAVNET project is funded by FAPESP (Proc. 06/02979), and
274 received partial funds from CNPq (490124/2006-2), and Centre National de la
275 Recherche Scientifique (CNRS). SAVNET has been participating to the International
276 Heliophysical Year program (IHY) activities.

Figure Captions

389

390

391 Figure 1: Examples of VLF propagation paths from transmitters NPM and NAA, to the
392 receiver bases of the SAVNET array in Brazil, Peru, Argentina and the Antarctic
393 continent.

394

395 Figure 2: Examples of solar flares detected by the SAVNET array using the VLF
396 propagation path NPM - ATI. One hour time duration soft X-ray fluxes (dash-dot) are
397 compared to the phase excesses (3 s time integrated noisy full line). The date and the
398 GOES Class of the event are indicated as well as the mean solar zenith angle along the
399 propagation path at the time of each solar event. The vertical thick lines represent a
400 phase excess of 15 degrees. Note the very small solar flare in the upper left corner.
401 Such an event does represent the power detection lower limit.

402

403 Figure 3: Solar flare probability detection P , as a function of the soft X-ray peak flux P_x
404 for the long NPM - ATI VLF propagation path, and for solar zenith angle greater
405 (dashed line) or lower (full line) than 40 degrees.

406

407 Figure 4: Correlation $\log [P_x]$ as a function of the mean Lyman- α solar flux. Numbers
408 refer to the reference works listed in the right column of Table 1.

414

415 Table 1 – Review of previous works as well as the present study (right column) on the statistical
416 relation between sudden phase anomaly and the strength of solar X-ray flares. The VLF propagation paths
417 as well as their length and frequency of observation are indicated in the left column. In the second column
418 (from left) we indicate the estimated value of P_{xm} . The third column shows the period of observation and
419 an average of the Lyman- α photon flux during the same period.

VLF propagation path properties	P_{xm} ($\mu\text{W}/\text{m}^2$)	Epoch, number of events, mean Ly- α flux (10^{11} ph.cm 2 .s $^{-1}$)	Reference
NAA - SP (7.87 Mm, 17.8 kHz) NWC - SP (14.7 Mm, 22.3 kHz)	4 (C4)	1968 50 events 4.9×10^{11} ph.cm 2 .s $^{-1}$	Kaufmann and Paes de Barros, 1969 (1)
NWC-Tananarive (6.89 Mm, 22.3 kHz)	3.4 (C3.4)	12/1968 - 01/1971 464 events 4.9×10^{11} ph.cm 2 .s $^{-1}$	Comarmond, 1977 (6)
GBR - Naini Tal (6.89 Mm, 16 kHz)	2 (C2)	04/1977 - 05/1983 111 events 4.6×10^{11} ph.cm 2 .s $^{-1}$	Pant et al. 1983; Pant, 1993 (3)
ARG-ATI (2.88 Mm, 10.2 kHz)	5 (C5)	1987 - 1989 463 events 4.98×10^{11} ph.cm 2 .s $^{-1}$	Kaufmann et al. 2002 (2)
NPM-Dunedin (8.1 Mm, 21.4 kHz) NLK-Dunedin (12.3 Mm, 24.8 kHz)	1 (C1)	1994 - 1998 ~ 100 events 4.2×10^{11} ph.cm 2 .s $^{-1}$	McRae and Thomson, 2004 Thomson et al., 2005 (4)
HAI-ATI (13 Mm, 13.6 kHz) NDAK-ATI (9.3 Mm, 13.6 kHz) ARG-ATI (2.88 Mm, 12.9 kHz) HAI-INU (6.1 Mm, 13.6 kHz) NDAK-INU (9.14 Mm, 13.6 kHz) LR-INU (10.97 Mm, 13.6 kHz) NWC-INU (6.99 Mm, 22.3 kHz) L-INU (14.48 Mm, 13.6 kHz)	0.6 (B6)	1994-1995 202 events 3.9×10^{11} ph.cm 2 .s $^{-1}$	Pacini, 2006 (7)
NAA-Belgrade (6.56 Mm, 24 kHz)	0.9 (B9)	07/2004-07/2005 114 events 4.11×10^{11} ph.cm 2 .s $^{-1}$	Zigman et al. 2007 (5)
NPM-ATI (13.07 Mm, 21.4 kHz)	0.27 (B2.7)	05/2006-07/2009 471 events 3.55×10^{11} ph.cm 2 .s $^{-1}$	This work (8)
